Abstract

Ultrasound guided regional anaesthesia is becoming increasingly popular. The supraclavicular block has been transformed by ultrasound guidance into a potentially safe superficial block. We reviewed the techniques of performing supraclavicular block with special focus on ultrasound guidance.

Keywords: supraclavicular block, regional anaesthesia, ultrasound, complications

Introduction

With increasing emphasis on patient safety and better patient outcomes, ultrasound guided regional anaesthesia [UGRA] is becoming more and more popular. Ultrasound provides clinicians with a real time image useful for visualizing anatomical structures, needle placement and local anaesthetic spread. Supraclavicular brachial plexus block provides consistently effective anaesthesia to the upper extremity [1,2]. This review focuses on ultrasound guided supraclavicular block, which is currently undergoing a renaissance.

Anatomy of supraclavicular brachial plexus

The primary ventral rami of C5 and C6 unite near the medial border of the middle scalene muscle to form the superior trunk of the brachial plexus [2]. The C7 ramus becomes the middle trunk; and C8 and T1 rami unite to form the inferior trunk. Variable contributions may arise from C4 and T2. Both the brachial plexus and the subclavian artery lie on top of the first rib. The three trunks undergo division at the lateral border of the first rib. The anterior divisions of the superior and middle trunk form the lateral cord, the posterior divisions of all three trunks form the posterior cord and the anterior division of the inferior trunk forms the medial cord. Seven different configurations of the brachial plexus have been described [2]. In the supraclavicular fossa, the brachial plexus is located lateral and superficial to the subclavian artery. The subclavian vein and anterior scalene muscle are found medial to the subclavian artery. The pleura is usually found within 1-2 cm from the brachial plexus [3].

The supraclavicular block is performed at the distal trunk/proximal division level, where the brachial plexus is most compact. This may explain its historical reputation for providing fast onset and complete, reliable anaesthesia for the upper limb, and the nickname ‘spinal of the arm’.

Anatomical Landmark technique and Nerve Stimulation technique

Initially described by Kulenkampff and Persy [4] in the early 20th century, the supraclavicular approach to the brachial plexus provides more consistent and effective regional anesthesia to the upper extremity than other
approaches to brachial plexus blockade [5]. As originally described, this technique requires the insertion of a needle toward the first rib where the brachial plexus lies in close proximity to the subclavian artery. Many modifications of this technique have been developed [6,7]. The most important modification is the “plumb bob technique” [8]. In this technique the point of needle insertion is at the junction between the superior edge of the clavicle and the most lateral part of the sternocleidomastoid muscle. The needle direction is antero-posterior. If brachial plexus contact is not achieved by the initial needle pass, the needle may be redirected cephalad in small steps up to 20° or 30° and subsequently caudal up to 20° or 30°, while staying in the sagittal plane through the initial needle entry site. All anatomical landmark methods used paraesthesia as a method of identification of the brachial plexus.

Localization of brachial plexus using nerve stimulator led to more effective and reliable blocks, but the risk of complications remained high [9].

Traditionally, supraclavicular blocks were associated with a high risk of complications including pneumothorax, phrenic nerve block, intravascular injections and Horner syndrome [7].

Ultrasound guided supraclavicular block:

Ultrasound guidance provides real time images, thereby in appropriately trained and experienced hands, has the potential to minimize the risk of complications.

The first literature description of the use of ultrasound for supraclavicular block was by La Grange and colleagues in 1978 for needle positioning [10]. Kapral et al were the first to report direct needle, plexus and local anaesthetic visualization. Using a 7.5MHz probe, orientated 3cm sagittally above the midpoint of the clavicle, their success rate was 95% [11]. Chan et al is credited with popularizing the technique [12]. The placement of catheters for continuous supraclavicular nerve block was first described by Yang et al [13].

Image acquisition

After skin and transducer preparation, a linear 38-mm, high frequency 10-15 MHz transducer is placed firmly over the supraclavicular fossa in the coronal oblique plane to obtain the best possible transverse view of the subclavian artery and brachial plexus. The patient is supine facing the contralateral side (fig 1). Nerves in the supraclavicular region appear hypo-echoic and are round or oval. The brachial plexus is located lateral and superficial to the pulsatile subclavian artery and superior to the first rib. The subclavian artery is identified first (fig 2), the subclavian vein lies more medially. The first rib is identified as a hyper-echoic structure lying deep to the vessels, and giving a bony shadow (dropout). The brachial plexus is consistently found lateral and superficial to the subclavian artery and above the first rib (fig 3).

Needling

In plane approach (Lateral to medial). This is the recommended approach, as the subclavian artery may traverse the brachial plexus. Ultrasound is useful, as Doppler can be used to identify the vessels (fig 2). For the in plane approach, a 5 cm 22G insulated block needle is inserted under sterile conditions on the outer (lateral) end of the ultrasound transducer (5-12 or 6-13 MHz) after skin local anaesthetic infiltration. The brachial plexus is identified as a compact group of nerves, sometimes compared to ‘a bunch of grapes’, located over the first rib, lateral and superficial to the subclavian artery. The rib and pleura are identified before needle insertions. The needle is advanced along the long axis of the transducer in the same plane as the ultrasound beam (fig 3). This way, the needle shaft and tip can be visualized in real time as the needle is advanced towards the target nerves. The identity of the nerves may be confirmed by electrical stimulation if desired. Useful stimulation endpoints for surgery proximal to the elbow are biceps and triceps twitches; hand muscle twitches are more appropriate for surgery distal to the elbow. Local anaesthetic solution is injected so as to cause hydro dissection of the planes around the plexus (fig 4, fig 5). The volume of local anaesthetic used is usually between 25 to 40 ml.

In plane (medial to lateral) approach may also be used based on user comfort.

Discussion

Efficiency of ultrasound guided supraclavicular blocks:
Arcand et al compared ultrasound guided supraclavicular to ultrasound guided infraclavicular block and demonstrated that surgical anesthesia was similar in both groups although the radial nerve required more frequent supplementation in the infraclavicular group [5]. A retrospective review of ultrasound guided supraclavicular blocks at Toronto Western Hospital revealed a success rate of 94.7% at first attempt; 2.8% required local anesthetic supplementation of a single peripheral nerve territory; and 2.6% received an unplanned general anesthetic. No cases of clinically symptomatic pneumothorax were noted. Complications included symptomatic hemidiaphragmatic paresis (1%), Horner syndrome (1%), unintended vascular punctures (0.4%), and transient sensory deficits (0.4%) [14]. Koscielniak-Nielsen ZJ et al conducted a study in 120 patients after randomizing them into ultrasound guided supraclavicular and ultrasound guided infraclavicular block. They found similar performance times. Block effectiveness was superior in the infraclavicular group compared to the supraclavicular group, 93% vs. 78%, P=0.017 [15]. The supraclavicular group patients had a significantly poorer block of the median and ulnar nerves, but a better block of the axillary nerve. Sensory scores at 10, 20 and 30 min were not significantly different [15]. Sainz Lopez et al conducted a study in 200 patients who had an ultrasound guided supraclavicular block for hand and elbow surgery. They concluded that efficacy was 98% [not requiring general anaesthesia] and no persistent complications were observed [16]. In the study by Kapral et al [11] ultrasound guided supraclavicular block was compared to ultrasound guided axillary block. No difference in surgical anaesthesia was found between the two groups of 20 patients, although the musculocutaneous nerve was only blocked in 75% of the axillary group compared to 100% in the supraclavicular group.

Ultrasound versus ultrasound plus nerve stimulation technique:
Williams et al examined supraclavicular block with either ultrasound alone or ultrasound with nerve stimulator, and noted faster block performance time with ultrasound alone and no difference in onset or success of sensory and motor block [1]. In a review of 104 patients scheduled for hand surgeries using ultrasound and nerve stimulation by Tsui et al, surgical regional anaesthesia was achieved in 94.2 % of the cases with an onset time of 20.2 +/- 9.2 min [17].

Paediatric ultrasound guided supraclavicular blocks
There have been numerous reports on the successful use of UGRA in children. De Jose Maria et al compared eighty children between 5-15 years undergoing upper limb surgeries [18]. Forty children were randomly allocated to two groups. One group received ultrasound guided supraclavicular block and the other group received ultrasound guided infraclavicular block. In the supraclavicular brachial plexus blocks, the duration of the sensory block was 6.5 +/- 2 h and that of the motor block was 4 +/- 1 h. Eighty eight % of blocks achieved surgical anaesthesia in the infraclavicular group without any supplemental analgesia, compared with 95% in the supraclavicular group. Failures in supraclavicular group were due to insufficient ulnar sensory block. No pneumothorax or

Horner’s syndrome were recorded in either group. The authors concluded that supraclavicular approach of the brachial plexus was less time-consuming than the infraclavicular approach [18].

**Potential advantages of ultrasound guided supraclavicular nerve blocks**

In general, ultrasound guidance results in local anesthetic dose reduction. However, in a well conducted study, the minimum volume required for ultrasound guided supraclavicular block in 50% of patients was 23 mL, and in 95% of patients was 42 mL of a local anesthetic mixture (50:50 mixture of lidocaine 2% and bupivacaine 0.5% with epinephrine) [20].

This may be a function of the rather ‘conservative’ approach to supraclavicular block, such as that depicted in figures 4 and 5. Most practitioners would agree that breaching the brachial plexus sheath at supraclavicular level does not constitute intraneural injection. It may result in a closer approximation of the needle and local anesthetic to the effector site, thus leading to a faster onset and perhaps better success rate [21].

The area infero-medial to the plexus, postero-lateral to the subclavian artery and superior to the first rib, is commonly referred to as ‘the corner pocket’ [22]. Despite suggestions that depositing local anaesthetic initially here (similar to figure 4) may be associated with a better ulnar block, one study found an unacceptably high-rate of ulnar sparing using this approach [22].

Our current understanding is that the needle should be redirected as needed to ensure the entire plexus is surrounded by local anesthetic for the best success rate.

Larger number studies are needed to prove that ultrasound guided supraclavicular blocks reduce the risk of complications when compared to traditional methods [23]. The trend so far is towards less complications (table I).

### Conclusion

The recent renewed interest in ultrasound guided supraclavicular blocks may be due to i) easy image acquisition relating to the superficial location of the brachial plexus at this level and ii) identifying the pleura thus minimizing the risk of pneumothorax. Beyond these, all the other attractive features of ultrasound guided peripheral nerve block apply.
