The appropriate prescribing of antibiotics is a challenge in primary care1,2. We performed an interventional trial to determine if providing an information leaflet on antibiotics with a delayed antibiotic prescription influenced the patients' decision to use the antibiotic for a respiratory tract infection (RTI). The control group (n=69) where a delayed antibiotic prescription and the intervention group (n=46) were given an information leaflet on antibiotics with the delayed prescription. In the control group, 72% (n=50) of patients indicated they subsequently used the antibiotic, and in the intervention group, 43% (n=20) indicated they used the antibiotic, this difference was statistically significant (p = 0.0018). The key conclusion of this study is that delayed prescriptions should be issued with an appropriate information sheet.

Introduction

The majority of respiratory tract infections (RTIs) are self-limiting, and do not require antibiotic treatment. A delayed prescription is given to the patient with the understanding that it is only to be used if specific symptoms worsen or if there is no improvement within a defined period of time. Use of a delayed antibiotic prescription has been suggested as a tool to reduce the inappropriate use of antibiotics and potentially have a positive impact in preventing antibiotic resistance. A patients' decision to fill the prescription and use the antibiotic may be influenced by how the delayed prescription is explained in the consultation. Written information regarding the appropriate use of antibiotics could be used to improve patient education and thereby reduce the number of prescriptions filled. The aim of the study was to examine the use of delayed prescriptions for RTIs, and to determine if concurrently providing the patient with an information leaflet on the appropriate use of antibiotics in RTIs and their potential side effects influences the rate of antibiotic use.

Methods

This was an intervention trial design. Ethical approval was obtained from the TCD/HSE GP Training Scheme Ethics Committee. The control group (n = 69) were given a delayed prescription for RTI, and the intervention group (n = 46) were given a delayed prescription with an accompanying information leaflet. The study was conducted in a Training Practice with four doctors. Basic demographic information was recorded for each patient given a delayed prescription. Data for the control group was recorded over a 5 week period and then the intervention group over a consecutive 5 week period. All patients presenting with RTI during the defined periods were included in the study. Verbal consent was obtained during the consultation. Data was collected by the treating Doctor in the practice, including current patient contact details. Each patient was subsequently contacted by telephone at 10-14 days post consultation, and asked if they had used the antibiotic on the delayed prescription.

Results

A total of 115 delayed prescriptions were presented; 69 in the control group (delayed prescription alone) and 46 in the intervention group (delayed prescription and information sheet). Both the proportion of fee paying versus primary care service eligible patients (65:50), together with the range of patient age indicated a robust degree of case mix, typical and representative of routine General Practice consulting. In the control group, 72% of patients used the delayed prescription and in the intervention group, 43% indicated they used the antibiotic, which difference was statistically significant (p = 0.0018), indicating that use of an information leaflet with delayed prescription was effective in very significantly reducing use of antibiotics. This effect was most evident among fee paying patients, who were less likely to use the antibiotic in both groups (Figure 1).

Discussion

Appropriately reducing the use of antibiotics for self limiting viral infections continues to be an important objective in routine prescribing. This study observes the impact of a simply designed practice information sheet on when it is appropriate to use an antibiotic, what steps should be taken to manage self care, and how an accompanying information sheet may influence a patient's decision to self medicate appropriately. This study demonstrates that use of an accompanying information leaflet is highly effective at reducing the use of antibiotics in delayed prescribing. It supports the uniform use of such leaflets in a routine study utilizing an interventional trial methodology on a small sample. It is proposed to conduct a larger block randomised control trial in order to confirm the approach can be generalised.
