Abstract

AIM: To evaluate published trials examining oral post-operative protein supplementation in patients having undergone gastrointestinal surgery and assessment of reported results.

METHODS: Database searches (MEDLINE, BIOSIS, EMBASE, Cochrane Trials, Cinahl, and C Abe), searches of reference lists of relevant papers, and expert referral were used to identify prospective randomized controlled clinical trials. The following terms were used to locate articles: “oral” or “enteral” and “postoperative care” or “post-surgical” and “proteins” or “milk proteins” or “dietary proteins” or “dietary supplements” or “nutritional supplements”. In databases that allowed added limitations, results were limited to clinical trials that studied humans, and publications between 1990 and 2014. Quality of collated studies was evaluated using a qualitative assessment tool and the collective results interpreted.

RESULTS: Searches identified 629 papers of which, following review, 7 were deemed eligible for qualitative evaluation. Protein supplementation does not appear to affect mortality but does reduce weight loss, and improve nutritional status. Reduction in grip strength deterioration was observed in a majority of studies, and approximately half of the studies described reduced complication rates. No changes in duration of hospital stay or plasma protein levels were reported. There is evidence to suggest that protein supplementation should be routinely provided post-operatively to this population. However, despite comprehensive searches, clinical trials that varied only the amount of protein provided via oral nutritional supplements (discrete from other nutritional...
components) were not found. At present, there is some evidence to support routinely prescribed oral nutritional supplements that contain protein for gastrointestinal surgery patients in the immediate post-operative stage.

CONCLUSION: The optimal level of protein supplementation required to maximise recovery in gastrointestinal surgery patients is effectively unknown, and may warrant further study.

Key words: Protein supplementation; Gastrointestinal surgery; Clinical trial; Oral supplementation; Systematic review

Core tip: Malnutrition in hospitalized patients can negatively impact recovery; protein and energy deficiencies have been documented in gastrointestinal surgery patients and trials have demonstrated benefits of peri-operative nutritional strategies, although post-operative oral nutritional supplementation have been studied to a lesser extent. The outcome of our work is that clinical trials that varied only the protein provided via oral supplements were not found. There is evidence to support oral protein supplements for gastrointestinal surgery patients immediately post-operatively. But the optimal level of protein supplementation required to maximise recovery in gastrointestinal surgery patients is effectively unknown, and may warrant further study.

INTRODUCTION

Malnutrition has been associated with increased incidence of complications such as sepsis, pneumonia, wound infections, clotting disorders, and wound dehiscence\(^2^,\(^3\)\). Patients undergoing major gastrointestinal surgery can suffer periods of undernourishment, not only as a consequence of their presenting illness, but also due to reduced food intake and the resulting catabolic state that prevails in the post-operative period. In this population, malnutrition has been found to increase post-operative morbidity and mortality rates as well as the duration and subsequent cost of hospital stay\(^2^,\(^4\)\). These despite multimodal nutritional regimens, include pre-operative carbohydrate loading.

In this context, nutritional supplementation has been suggested as a routine post-operative procedure for gastrointestinal surgery patients given the putative negative nitrogen balance. Indeed, intervention in the form of post-operative protein supplementation (in the context of allowable free-fluids or light diet by mouth) has remained of interest as an effective way to improve patient recovery despite an apparent paucity of trials adequately addressing the optimum, or even appropriate, quantity of proteins or peptides. As the physiological nitrogen balance is affected by both energy and protein consumption, knowledge of the levels of each that best enable avoidance of catabolic loss after gastrointestinal surgery could benefit patient outcomes\(^5\).

Therefore, in this review, clinical trials of oral nutritional supplements providing increased protein levels relative to controls, administered to human patients recovering from gastrointestinal surgery, were systematically assessed with respect to clinical efficacy and cost-effectiveness.

MATERIALS AND METHODS

Search methods

The following terms were used to locate articles: “oral” or “enteral” and “postoperative care” or “post-surgical” and “proteins” or “milk proteins” or “dietary proteins” or “dietary supplements” or “nutritional supplements”. In databases that allowed added limitations, results were limited to clinical trials that studied humans, and publications between 1990 and 2014. Despite these limits, multiple non-clinical trial results, non-human trials, and irrelevant studies appeared and were excluded. The search was intentionally broad as more specific searches for gastrointestinal surgery associated keywords and MeSH terms resulted in numerous missed relevant papers. Databases searched included: MEDLINE, Biosis, EMBASE, Cochrane Trials, Cinahl, and CAB. Other means of identifying records included searching reference lists of relevant papers.

Inclusion and exclusion criteria

Randomized controlled clinical trials examining protein-based oral dietary supplementation post-operatively in human gastrointestinal surgery patients were selected. Studies were excluded if: Involved immunonutrition; related to supplementation with incomplete proteins; did not specify the amount of protein supplemented; supplemented patients pre-operatively only; not strictly oral nutrition; or not published in English.

Outcomes measured

Primary outcomes included the effect of supplementation on post-operative complications, length of hospital stay, nutritional status, and weight loss. Secondary outcomes included the effect on plasma proteins, quality of life, function, and cost of care.

Data collection and analysis

Trials that met the inclusion criteria were independently assessed for eligibility by the authors (Crickmer M, O’Regan A, Dunne CP) and discrepancies were resolved
by discussion. Papers were read independently by the authors and themes were identified. Risk of bias was assessed by determining allocation concealment for participants, the staff and assessors. The effect of treatment was assessed relative to clinical importance and statistical significance, using $P$ values of $\leq 0.05$ as the cut-off point. The evaluation of the trials was guided thematically with the qualitative tool, modified from a previous Cochrane Systematic Review\[6\], described in Tables 1 and 2. The characteristics of each study were tabulated and are shown in Table 3.

Where studies included both pre- and post-operative supplementation interventions, only the post-operative components are considered in this review. The numbers of trial participants per study were adjusted to reflect this.

**RESULTS**

**Results of the search**

Following PRISMA guidelines\[7\], seven eligible reports were identified (see Figure 1). Exclusions were as follows: (1) of records found via database searching: 358; (2) of records found by other means: 271; (3) of records screened: 629; (4) of records excluded (including removal of duplicates): 587; (5) of full text articles assessed for eligibility: 42; (6) of full text articles excluded: 35; and (7) of studies included in qualitative analysis: 7.

**Assessment of studies design**

All seven studies\[5,8-13\] were prospective randomized controlled trials. In most cases, the patients, their carers and the assessors were not blinded. Intention to treat was not included in most studies. The control and intervention groups had similar characteristics in each trial and in all other aspects of treatment, other than the intervention. The interventions undertaken, and inclusion and exclusion criteria, were well defined in all studies. Five of the seven studies\[5,8,9,11,13\] included outpatient phases that lasted between one and six months. The characteristics of the studies are outlined

Table 2 Outcomes of quality assessment, described for individual trials

in Table 3.

**Sample sizes and patient population**
Sample sizes ranged from 40 to 101. A total of 529 patients were involved, 262 of whom had an intervention. Participants were post-operative gastrointestinal surgery patients scheduled for acute or elective surgery. Nutritional status pre-operatively was variable, with some studies focused on malnourished patients[10,13]. Patient age ranged from 18 to greater than 75, and all studies included both genders.

**Interventions**
All treatment group (TG) patients received post-operative nutritional supplementation in addition to their normal ward diet, while control groups (CGs) consumed only normal ward diet. In most cases, patients were encouraged to drink 200-400 mL of the supplement per day. Supplements comprised between 0.0078 g/mL and 1.5 kcal/mL of protein, with the most frequent value being 0.05 g/mL. They also provided between 0.0078 g/mL and 0.06 g/mL of protein, with the most frequent value being 0.05 g/mL. Supplements comprised between 0.0078 g/mL and 1.5 kcal/mL of energy, with the most common inclusion being 1.5 kcal/mL. All studies, except Jensen[5], began supplementation as soon as allowed by the surgical team, typically beginning one to six days post-operatively. Some studies focused on post-operative feeding only, while studies by Smedley et al[8] and MacFie et al[5] examined both pre-operative and post-operative feeding. Only the post-operative component of those studies is considered in this review and the numbers of trial participants has been adjusted to reflect this.

**Themes**
Assessment was according to the following eight themes:

- **Overall nutritional intake**: Four of the studies quantified the difference in protein intake between treatment and CGs. Specifically, Saluja et al[10] found that protein intake was significantly higher (P < 0.01) in the group given supplementation in addition to ward diet. The TG consumed an average of 55.71 ± 11.63 g of protein per day during the study period, while the CG consumed 39.48 ± 11.14 g of protein per day (P < 0.01). These increases in protein consumption were accompanied by significant increases in the amount of carbohydrate consumed (P < 0.01). Jensen et al[3] calculated that the TG consumed 22% more protein than the CG and 16% more energy. It is noteworthy that supplementation in that trial started after discharge at about day 10, and was paired with dietetic advice, while in the previous trial by Saluja et al[10], supplementation began the first day following surgery. Keele et al[11] also found that the TG showed statistically significant increases in protein and energy consumption on study days one to four.

No difference in protein intake was seen in the second phase of their trial, which examined intake for 4 mo following discharge. The inpatient results (improved overall nutritional intake) found by Rana et al[12] are similar to those found by Keele et al[11].

- **Weight**: Four of five studies that measured this factor[5,8,11,12] found reduced weight loss in normonourished patients receiving supplementation. Keele et al[11] found decreased loss both at day 3 of the trial and at discharge (P < 0.001). Rana et al[12] found that when patients started supplements as soon as they were allowed free fluids after surgery, they maintained their weight whereas by day 3, there was significant weight loss in the CG (P < 0.05). Statistically significant reduction in weight loss was also found by Smedley.

</table>
Beattie *et al.*[^13] PRCT Patients had a BMI < 20 or > 5% weight loss between hospital admission and trial inclusion, and other anthropometric criteria. Age: 18-80

$n = 101$, intervention $= 52$; control $= 49$

Oral nutritional supplement containing 0.06 g/mL protein, 1.5 kcal/mL energy. Patients encouraged to consume 400 mL/d postoperatively. In practice, patients had between 200 and 400 mL/d in addition to normal meals

Weight loss: CG lost an average maximum of 5.96 kg at 8 wk after admission, while TG lost a maximum of 3.4 kg on average in the first 4 wk and then gained weight ($P < 0.001$)

Mean body weight loss = 9.8% in CG and 5.6% in treatment group

Triceps skin fold and MAMC were higher in TG than CG ($P < 0.001$) Function: Improved grip strength at 10 wk ($P < 0.001$)

Quality of life (UK SP-36): Statistically significant improvement in mental and physical health ($P < 0.001$)

Complications: Reduced ($P < 0.05$)

No difference in infection rates

Length of stay: No difference

Mortality: No difference

Possible lack of difference due to small study numbers in each group, or in general, early return to eating post-surgery in practice along with dietitian support normally at the hospital

Jensen and Hessov[^5] RCT - Supplements given after discharge from colorectal surgery for 4 mo

Elective and acute $n = 87$-47 in CG and 40 in TG

Control group: Discharged without advice

Body mass: (50 d after discharge) lean body mass increase seen in TG of 1.3 kg ($P = 0.009$) and in overall body mass 2.0 kg ($P = 0.005$). 110 d after discharge: Total mass difference was +2.7 kg for TG relative to CG ($P = 0.014$), and lean body mass +1.4 kg for TG ($P = 0.029$)

No significant difference in fat mass was seen at either stage

TG: Dietetic advice and a variety of supplements including protein only - aiming for 1.5 g protein/kg per day

Serum albumin: No difference was seen at any time

Recommendation: Patients should increase protein intake to 1.5 g/kg per day for 2 mo post-surgery

MacFie *et al.*[^9] PRCT Major GI surgery patients $n = 52$; 27 had intervention of some kind.

TG $n = 27$ (post op supplements), CG $n = 25$

Pre and post-operative phases. For this review, only the control group and post-operative supplementation group were looked at

Fortisip, Nutricia given - 0.05 g/mL protein and 1.5 kcal energy/mL or an alternative Fortijuice, Nutricia containing 0.025 g/mL protein and 1.25 kcal/mL energy. Patients encouraged to consume 400 mL/d in addition to normal ward diet

Supplementation commenced as soon as permitted fluids post-surgery, usually within 24 h

CG was provided standard ward diet

Nutritional intake: Increased protein and energy seen (but no benefits could be seen)

Morbidity: No difference

Also concluded: No difference in benefit when looked at the 17 malnourished patients in the study

Nutritional status: No difference

Functional status: No difference

Hospital stay: No difference

Weight Loss: No significant difference

Serum albumin: No significant difference

Psychological Status: No significant differences

Return to normal activities at 6 mo: No difference

No evidence that increased supplements decreased amount of ward diet eaten

Similar intakes of supplements as previous trials (Rana, Keele) that showed benefit

Support for nutritional intervention in patients with malnutrition:

Post-operative oral nutritional supplementation improved nutritional status, quality of life and morbidity

Crickmer *et al.* Post-operative oral protein supplementation: Systematic review of trials

[^9]: RCT - Supplements given after discharge from colorectal surgery for 4 mo

[^13]: PRCT - Patients had a BMI < 20 or > 5% weight loss between hospital admission and trial inclusion, and other anthropometric criteria.
Keele et al.[11] Short and long term (4 mo after discharge) benefits of intervention

(There were four groups in this study: C/C had no supplementation before/after surgery; C/S had none before and supplementation after; S/C had supplementation before and none after; S/S had supplementation before and after surgery.

For the purposes of the review C/C were taken as CG and C/S were taken as TG)
et al\(^{[9]}\) (\(P < 0.05\)). In the trial by Jensen et al\(^{[5]}\), supplementation was not started before discharge, typically around 10 d post-operatively, but at both 50 and 110 d after discharge, the intervention group had increased total and lean body mass. No other studies looked specifically at lean body mass. Conversely, however, MacFie et al\(^{[9]}\) reported no significant difference in weight loss between control and intervention groups overall.

Studies by Saluja et al\(^{[10]}\) and Beattie et al\(^{[13]}\) noted reduced weight loss in the malnourished patient population investigated in their studies, but no difference was seen by MacFie et al\(^{[9]}\) when he isolated the 17 malnourished patients from his study. More specifically, Beattie et al\(^{[13]}\) found that controls lost an average of 5.96 kg in 8 wk, while intervention patients lost 3.4 kg on average in the first 4 wk and then gained weight (\(P < 0.001\)). Saluja et al\(^{[10]}\) quantified the average weight loss in the TG as 2.15 kg compared to 4.6 kg in the CG (\(P < 0.01\)).

**Postoperative complications:** None of the studies found a difference in mortality between control and TGs. A wide variety of other complications were looked at including chest and wound infection, sepsis, cardiac arrest, pulmonary embolism, and wound dehiscence. Three of the 6 trials that investigated complications found a reduced number in the TG: Smedley et al\(^{[10]}\) found reduced minor complications (\(P < 0.05\)) but no difference in major complications. Both Keele et al\(^{[11]}\) and Rana et al\(^{[12]}\) demonstrated significantly fewer serious complications in their short term studies (\(P < 0.05\)). No difference in post operative complications was found by Saluja et al\(^{[10]}\) or MacFie et al\(^{[9]}\). Saluja et al\(^{[10]}\) did find a reduction in infectious complications in severely malnourished patients, but numbers were too small for statistical significance. Similarly, Beattie et al\(^{[13]}\) saw a reduction in complications that was not significant when adjusting for age and sex.

**Table:** Comparison of postoperative outcomes between intervention and control groups.
Length of stay: The study by Saluja et al.\(^ {10}\) determined a difference in length of stay between treatment and CGs in severely malnourished patients, but no difference in moderately or borderline malnourished patients. Beattie’s study\(^ {13}\), which also looked at malnourished patients, found no difference. The three studies\(^ {8,12,13}\) that evaluated length of stay in normonourished patients found no difference.

Plasma proteins: Four studies investigated plasma proteins levels\(^ {5,9,10,12}\), with albumin the focus of most of these studies. None of these found any significant difference in serum albumin or prealbumin. Rana et al.\(^ {12}\) found increased retinol binding protein in the TG relative to controls at day three (\( P < 0.05 \)).

Cost: Smedley et al.\(^ {8}\) found that the use of oral nutritional supplementation, irrespective of when administered, decreased cost by £300 (sterling) per patient amounting to a 15% reduction compared to patients without supplementation. This was not statistically significant. No other study considered cost of care.

Grip strength: Three of five studies that investigated grip strength found reduced loss of grip strength in patients receiving oral nutritional supplements relative to controls. Keele et al.\(^ {11}\) found that handgrip was maintained in the intervention group and significantly reduced in controls (\( P < 0.01 \)). Rana et al.\(^ {12}\) found a significant difference at day three and again at discharge (\( P < 0.05 \)). Beattie et al.\(^ {13}\) found similar results and noted statistical significance in the differences at week 10 (\( P < 0.001 \)). Saluja et al.\(^ {10}\) and MacFie et al.\(^ {9}\) detected no difference in hand grip strength after supplementation.

Quality of life and fatigue: Beattie et al.\(^ {13}\) found increased quality of life in the TG using the short form 36 questionnaire (SF-36)\(^ {14}\) in both mental and physical health (\( P < 0.001 \)). Smedley et al.\(^ {8}\) used SF-36 and EuroQol instruments to test quality of life and found no difference. Keele et al.\(^ {11}\) subjectively assessed fatigue and found significant increases in control patients at study day three (\( P < 0.001 \)), while TG increases in fatigue were not significant.

DISCUSSION

Previous reviews have concluded that oral nutritional supplements can have positive effects in terms of recovery of nutritional status post-operatively in conditions such as fractured neck of femur, colorectal surgery, and pancreaticoduodenectomy, among others\(^ {15-17}\). In these cases, the proposed benefits...
could be attributed to protein supplementation (i.e.,
the amount of orally-consumed protein that confers the
greatest benefit) combined with appropriate energy intake[19].
However, what these levels are remain unclear for
patients following gastrointestinal surgery. In this
review, we attempted to determine this via systematic
review.

Our searches did not yield a single randomized
controlled trial that adequately differentiated the
effect of protein supplementation from carbohydrate
supplementation. Therefore, analysis of the eligible
reports was problematic. Limitations included the fact
that protein and energy content in TG supplements
were not equivalent in most of the studies. Indeed,
only the study by Saluja et al[10] described using a
fixed amount of supplement for daily consumption,
while the remaining studies followed an "ad-libitum"
approach. Arguably, the latter approach best mirrors
"real-life" clinical scenarios, however it makes discerning
the true effect of protein supplementation difficult.
Furthermore, the characteristics of the patient cohorts
were not equivalent between studies, confounding
inter-study comparisons. For example, the study by
Saluja et al[10] took place in Delhi and included a greater
proportion of emergency surgery patients, and patients
with tuberculosis, compared with the non-emergent
procedures described in the Western European reports.
Moreover, inadequate follow up time with control and
TGs was common across studies, with some risk of bias
associated with lack of blinding of participants, carers
and assessors. The power of the studies was often too
small, with one author conceding notably that "numbers
were too small for meaningful statistical analysis"[13]
and intention to treat analysis was not used in any
of the studies. Finally, the most recent of the eligible
trials found in our searches was published in 2004,
arguably reflecting either a shift in interest away from
oral intake in favor of enteral and parenteral nutrition in
this population or an emphasis placed on ordinary diet
without supplement.

Despite these limitations, the authors of six of the
seven studies detailed weight loss in patients recei-
ving post-operative nutritional supplements, but to
a lesser degree than the loss in control patients[5,8,10-13].
In fact, the data suggest that this effect may be
most prominent in patients malnourished initially,
with statistically significant reductions in weight loss
observed. While one study failed to observe this effect[9],
despite similar energy and protein intakes to other
trials, the authors proposed that the lack of effect was
due to a small sample size. Finally, with respect to
weight gain post-operatively, it appears that weight
gain commenced sooner and patients appeared to
return to their preoperative weight more rapidly where
supplementation was provided.

There is no evidence to suggest that nutritional
supplementation post-operatively reduces mortality.
While more deaths did occur in the CGs of the reported
trials, much larger samples would be needed to
approach statistical significance. The topic of avoidance
of both serious and minor complications is less clear.
There is some precedent to suggest that post-operative
supplementation decreases complications, as the
effect has been documented in patients undergoing
hip surgery[15,10,20]. However, across the eligible studies
here, the rate of both serious and minor complications
was significantly reduced in four of the trials[9,11-13],
while no statistically significant difference was observed
in two[9,10]. This variation has been addressed somewhat by
Beattie et al[13] when comparing his results to the study
by MacFie et al[9] in making reference to discrepancies
in defining complications. On a related topic, duration
of hospitalization was reduced significantly in severely
malnourished patients only[10]. An additional study
that supplemented increased amounts of protein and
medium chain carbohydrates in enteral feed in gastroin-
testinal patients post-operatively found a 6-d reduction
on average (P < 0.05)[21]. However, that study had
larger numbers than any of the studies considered in
this review, with 229 total and 115 TG patients. It has
also been suggested that length of stay is a relatively
poor outcome to evaluate as it often depends on patient
social circumstances and services available in addition
to patient post-operative clinical condition[13].

With respect to malnutrition, and assessment of
patient incidence, low albumin has been used as a
measurable indicator; but evidence suggests that it is
not an effective marker of recent nutritional intake[22].
Approximately 5% of the circulating albumin is replaced
daily by the liver and, therefore, any changes in protein
intake would not be evident immediately. Further, protein
markers in the blood such as prealbumin, albumin and
transferrin are impacted by fluid shifts and responses
to injury and inflammation which complicate their
use in comparisons of patients before and after major
abdominal surgery, when tissue injury is present[23]. This
may explain why none of the studies in our review that
monitored albumin in the early post-operative period
found any disparity in albumin levels despite differences
in anthropometric indicators of malnutrition (e.g., triceps
skin fold, mid upper arm circumference and BMI[24]).
Similarly inconsistent results were found regarding
quality of life.

Evaluation of quality of life and physiological function
were similarly inconsistent. For example, handgrip
strength is a marker of function and results were variable
across the trials. However, those variances may be
explained by the use of dissimilar techniques for
measurement, and confounders such as pain and fatigue
post-operatively. Interestingly, the TGs in the studies
conducted by MacFie et al[9] and Saluja et al[10] both
described increased total body mass retention relative to
CGs, but without significant increases in grip strength.
Jensen et al[8] found that supplementation increased
lean body mass particularly, not simply fat mass, so
one could hypothesize that a functional measurement
Volume 8 | Issue 7 | www.wjgnet.com | WJGS | July 27, 2016 | 530
like grip strength would also be improved, but this was not described. Previous work has documented a link between impaired muscle function and nutritionally-related complications[24,25], but this was not consistently reflected across the eligible trials here.

The seven studies reviewed in this paper concurred that there is no difference in mortality seen with protein-inclusive nutritional supplements. There is evidence to suggest that weight reduction, nutritional intake, and nutritional status are improved, and that there may be positive cost of hospitalisation benefits, but evidence as to the effect on complications and grip strength is mixed. At present, there is some evidence to support routinely prescribed oral nutritional supplements that contain protein for gastrointestinal surgery patients in the immediate post-operative stage. However, randomized control trials using well-designed methodology to examine the optimal protein content needed to confer benefit are needed.

**COMMENTS**

**Background**

Malnutrition in hospitalized patients can negatively impact recovery; protein and energy deficiencies have been documented in gastrointestinal surgery patients and trials have demonstrated benefits of perioperative nutritional strategies, although post-operative oral nutritional supplementation have been studied to a lesser extent. The proposed benefits may be attributed to protein supplementation (i.e., the amount of orally-consumed protein that confers the greatest benefit) combined with appropriate energy intake. However, what those levels may be remain unclear for gastrointestinal surgery patients.

**Research frontiers**

The positive impact of pre-operative nutrition has been reviewed previously and meta-analyses have demonstrated positive influence on patient outcome following gastrointestinal surgery. In the postoperative period however, the most pertinent question may be whether patients should be further supplemented. The proposed benefits may be attributed to protein and energy deficiencies have been documented in gastrointestinal surgery patients.

**Innovations and breakthroughs**

The authors’ searches did not yield a single randomized controlled trial that adequately differentiated the effect of protein supplementation from carbohydrate supplementation. With only one exception, the eligible studies reviewed here involved post-operative supplements administered “ad-libitum”. Although this may best mirror “real-life” clinical scenarios, it makes discerning the true effect of protein supplementation difficult. Furthermore, the characteristics of the patient cohorts were not equivalent between studies. Despite these limitations, the authors of six of the seven studies detailed weight loss in patients receiving post-operative nutritional supplements, but to a lesser degree than the loss in control patients. There is no evidence to suggest that nutritional supplementation post-operatively reduces mortality and evaluation of quality of life and physiological function were similarly inconsistent.

**Applications**

An intervention based on oral protein supplementation should be investigated through a double-blind randomized controlled trial.

**Terminology**

There are no terms used that are uncommon and that would be unfamiliar to readers.

**Peer-review**

The authors have made a good collation of the data to assess if there are any benefits of post-operative protein nutritional supplementation following gastrointestinal surgery. The manuscript is well written and covers the salient points from the published studies.
